Abstract

Humans differ greatly in their tendency to discount future events, but the reasons underlying such inter-individual differences remain poorly understood. Based on the evolutionary framework of Life History Theory, influential models predict that the extent to which individuals discount the future should be influenced by socio-ecological factors such as mortality risk, environmental predictability and resource scarcity. However, little empirical work has been conducted to compare the discounting behavior of human groups facing different socio-ecological conditions. In a lab-in-the-field economic experiment, we compared the delay discounting of a sample of Romani people from Southern Spain (Gitanos) with that of their non-Romani neighbors (i.e., the majority Spanish population). The Romani-Gitano population constitutes the main ethnic minority in all of Europe today and is characterized by lower socio-economic status (SES), lower life expectancy and poorer health than the majority, along with a historical experience of discrimination and persecution. According to those Life History Theory models, Gitanos will tend to adopt “faster” life history strategies (e.g., earlier marriage and reproduction) as an adaptation to such ecological conditions and, therefore, should discount the future more heavily than the majority. Our results support this prediction, even after controlling for the individuals’ current SES (income and education). Moreover, group-level differences explain a large share of the individual-level differences. Our data suggest that human inter-group discrimination might shape group members’ time preferences through its impact on the environmental harshness and unpredictability conditions they face.

Keywords: Romani, delay discounting, impatience, adaptation, evolutionary psychology, life history
1. Introduction.

In nature, individuals of different species often have to choose between outcomes realized at different times (Ainslie, 1975; Rachlin & Green, 1972). These inter-temporal choices are also ubiquitous in the lives of humans, for instance, in the spheres of marriage and reproduction, education and work, as well as during social and market interactions (Espín et al., 2012, 2015; Frederick et al., 2002; Nettle et al., 2011; Woodburn, 1980). When faced with such decisions, individuals tend to discount the value of delayed rewards. The preference for sooner-smaller rewards over later-larger rewards has been referred to as delay discounting (DD) (Frederick et al., 2002; Kirby et al. 2002). DD is considered to be a measure of one of the multiple domains of impulsivity, namely “impulsive choice” (Bevilacqua & Goldman, 2013; Reynolds et al., 2006).

DD tends to be a stable individual characteristic (Ohmura et al., 2006; Kirby, 2009) – although it may be momentarily influenced by short-term state manipulations (e.g., Kidd et al., 2013; Read & van Leeuwen, 1998) – and people differ greatly in the extent to which they discount the future (Frederick et al., 2002). However, the factors underlying such inter-individual differences remain poorly understood. On the one hand, there is evidence suggesting that DD rates are heritable to some extent (Anokhin et al., 2011, 2015; Aycinena & Rentschler, 2017; Bevilacqua & Goldman, 2013). On the other hand, people’s current socio-economic conditions, as proxied by variables such as education and income, also seem to be related to DD: poorer and less educated individuals have been found to discount the future more heavily (Harrison et al., 2002; Kirby et al. 2002; Tanaka et al., 2010), although the causal direction is unclear (Becker & Mulligan, 1997). In addition, a number of behavioral disorders (e.g., attention-deficit/hyperactivity disorder, aggression, suicide, and
substance abuse) have been associated with high DD (Barkley et al., 2001; Bickel, & Marsch, 2001; Dombrovski et al., 2011).

The latter evidence has been taken to support the notion of high DD as a maladaptive trait. However, under certain socio-ecological conditions, discounting the future can be a contextually appropriate response. To be more specific, developing a preference for the short-run may be fitness-maximizing in harsh and unpredictable environments (Becker & Mulligan, 1997; Daly & Wilson, 2005; Frankenhuis et al., 2016; Hill et al., 2008; Pepper, & Nettle, 2017).

According to Life History Theory (Del Giudice et al., 2015; Kaplan & Gangestad, 2005; Roff, 1993), variation in life history traits (e.g., size and number of offspring, parental investment, longevity, time to first reproduction, sociability) can be understood in terms of trade-offs in the allocation of resources to competing life functions such as maintenance, growth, and reproduction. The accumulated set of resource allocation decisions during life constitutes the individual’s life history strategy, which leads to the development of an integrated collection of life history traits. The most common approach to life history strategies poses a continuum from slow to fast (Promislow & Harvey, 1990). Leading models based on Life History Theory rely on this slow-to-fast approach to predict variation of traits and strategies both between and within species. In this vein, unpredictable and harsh environments are particularly related to the development of fast life history strategies that divert resources from long-term outcomes in favor of short-term outcomes, while predictable and secure settings lead to strategies in the opposite, slow end of the continuum (Kaplan & Gangestad, 2005).

Life history strategies are often seen as species-distinctive characteristics but humans (as well as other organisms) have evolved mechanisms of phenotypic plasticity that allow them to
adjust life history strategies to match local conditions during their lifetime (Belsky et al., 1991; Brumbach et al., 2009; Ellis, 2004; McCullough et al., 2013; Nettle et al., 2010, 2011; Worthman, 2003). These strategies would lead to the maximization of individuals’ average lifetime inclusive fitness (Del Giudice et al., 2015; Kaplan & Gangestad, 2005; Roff, 1993).

However, it is worth noting that existing theories are almost entirely based on verbal models, or on formal models designed to study the evolution of variation in life history strategies between species/populations, which tend to ignore the plasticity in life history strategies within species/populations.¹ Few formal models to date have examined how suits of traits (e.g., onset of puberty, number of offspring, investment per offspring) should covary as a result of phenotypic plasticity (e.g., along a fast-slow continuum), depending on environmental conditions (Mathot & Frankenhuism, 2018). For pioneering verbal models of within-species/populations variation in life history traits along the fast-slow continuum, see Belsky et al. (1991), Ellis et al. (2009) and Reale et al. (2010).

Yet, although the theoretical literature on life history clearly stresses the role of environmental conditions in shaping individuals’ DD, more research needs to be conducted to assess this link empirically. While a number of individual-level studies provide support for the hypothesized relationships by showing, for example, a connection between high DD and variables such as low income and education, which can be considered as proxies for unfavorable (potentially harsh and/or unpredictable) conditions (Becker & Mulligan, 1997; Chipman & Morrison, 2015; Green et al., 1996; Griskevicius et al., 2011; Kirby et al. 2002; Pender, 1996), few studies to date have examined to what extent the conditions of harshness and future-unpredictability faced by different groups can predict individual differences in DD. Given that those individual-level studies do not use grouping variables that are

¹ We thank Reviewer 1 for pointing out this important issue.
exogenous to the individual, they cannot put the focus on an environment-based analysis, as prevails in the theoretical literature. Ramos et al. (2013) is, to the best of our knowledge, the first study directly approaching the question. Consistent with the theoretical predictions, the authors show that slum-dwelling youth in Brazil (highly exposed to violence) discount future hypothetical rewards more heavily than university students from more affluent neighborhoods. A more recent study enlarged the number of comparison groups (46 countries were used as observation units) and found that country-level life expectancy can predict the average DD in a sample of university students from the country (Bulley & Pepper, 2017), also as hypothesized by a life history approach. Finally, Lee et al. (2018) extended the latter analysis to a larger sample from 54 countries using individual-specific life expectancy (i.e., age-, sex-, year-, and country-specific life expectancy), and show that the theoretical relationship holds especially when waiting is arguably more beneficial, that is, when the later-larger reward is relatively high and delay is short. While these pieces of work have significant value, in the three cases, the authors compare groups of young individuals who, moreover, differ in a large number of uncontrolled characteristics that are not necessarily related to harsh and unpredictable living conditions but may influence DD. Among those are neighborhood facilities (which may translate into different access to services, for instance), geography, political regime, climate, and so forth. Furthermore, the tasks used to elicit the participants’ time preferences (i) did not allow for a parametrization of the individuals’ discount functions and (ii) were survey-based, without real incentives. In this paper we further contribute to fill this empirical gap.

To test the predictions of the evolutionary framework of Life History Theory, this study explores the differences in DD between two populations which often face different socio-ecological pressures even if they live in the same geographic areas, even in the same villages
and neighborhoods. More specifically, using data from an economic experiment involving real monetary rewards, we compare the discounting behavior of a sample of Romani people from Southern Spain (Gitanos, or Calé, as they typically refer to themselves) with that of their non-Romani neighbors (i.e., the majority Spanish population). Technically speaking, we set up a quasi-experimental design where ethnicity is the only variable that a priori differs between treatment and control groups. Note that a pure experimental design cannot be applied here because the socio-ecological conditions under which the individuals develop, as proxied by their ethnicity, cannot be exogenously manipulated for obvious reasons. We consider that this design is as close to a controlled experiment as a study of these characteristics can be since ethnicity and its associated socio-ecological conditions are eminently exogenous, thus leaving little room for endogenous determination.

The localities where we conducted our experiments are characterized by a particularly high concentration of Gitano people, amounting to over 25% of the total population, compared to 1-1.5% in the whole of Spain (Gamella, 1996; Gamella et al., 2014). However, the Gitano population is clearly differentiated in their demographic and cultural profile, and faces a markedly different socio-economic “ecology” than the majority. Hence it constitutes a paradigmatic ethnic group for the goal of this study. Notwithstanding this, it is worth noting that theoretically identical opportunities (Rawls, 1971; Sen, 1992) in terms of access to public education, social benefits and healthcare, are provided (at least legally, on paper) to the Gitano population, at least since the advent of democracy in Spain, four decades ago.

Compared to the dominant majority, the Gitano population of Spain is characterized by a lower socio-economic status (SES), including lower income and education, and also by

\[2\] Spanish Gitanos have been barely studied using experimental economics methods. We are only aware of two studies: Brañas-Garza et al. (2006) explores how Gitanos play the Ultimatum Game, while Espín et al. (2018) analyzes punishment in the Public Goods Game.
poorer health, lower life expectancy and higher fertility rates (Casals et al., 2011; Cook et al., 2013; Gamella, 2011; Gamella et al., 2014; La Parra Casado et al., 2016; MSC-FSG, 2005). These processes have generated a differentiated demographic profile. For instance, in the study area, the *Gitano* population had a mean age of 27 years compared to the near 42 of the overall local population (Gamella, 2011). Life expectancy at birth has increased in this population almost continuously since the mid 1940s. But still today it seems to be from 5 to 10 years below that of their non-*Gitano* neighbors (Gamella, 2011; MSC-FSG, 2005). This may have resulted in a different set of aggregated needs and outlooks.

However, despite a long-lasting coexistence in many local areas, social exclusion, forced assimilation and discrimination by the majority have considerably influenced the lives of *Gitanos* as well as of other Romani groups in almost every part of the world (Matras, 2015). In Spain this still affects the lives of *Gitano* people, particularly in the most segregated areas. Several distinctive features of *Gitano* social life seem to reflect adaptations to these negative environmental and historical conditions. For instance, *Gitanos* maintain a strong and oppositional sense of identity and high levels of ethnic and familial endogamy. In the study area the *Gitano* minority presented rates of inbreeding five to eight times larger than those of the general population, and have maintained these until the present (Gamella & Martín, 2007; Martín & Gamella, 2005; Núñez Negrillo, 2016). These endogamous strategies tend to increase their social and perhaps their genetic homogeneity (Bittles, 2012). However they also might work as a protection against external threats associated with the discriminatory environments that *Gitano* confronted as a group (Fraser, 1995; Gamella et al., 2013; Matras, 2015). Interestingly, the rate of incarceration of *Gitanos* is still nowadays much higher than that of the majority population. As an example, in a number of recent studies, *Gitano* women
accounted for over 25% of the female prison population, a huge over-representation (Cerezo, 2016; Feintuch, 2013).

In addition, most Gitano groups, as other Romani groups through Europe, also maintain patterns of early and pronatalist marriage. Gitano women in the study area were found to have a mean age of first childbirth of 18-19 years (over a decade earlier than the Spanish average), and total fertility rates that doubled and even tripled those of the Spanish population at large (Gamella, 2011; Martín & Gamella, 2005). Infant mortality rates displayed by Gitanos have declined sharply during the last 60 years but are still nowadays considerably larger (about 40%) than those observed in the non-Gitano population (Gamella & Martín, 2017; Martín & Gamella, 2005; MSC-FSG, 2005).

These patterns of Gitanos can be understood as life history strategies situated at the (relatively) fast end of the fast-slow continuum, which are typically adopted by people who grow up in unpredictable and harsh environments (Brumbach et al., 2009; Dickins et al., 2012; Frankenhuis et al., 2016; Johns et al., 2011). When the future is uncertain or predictably harsh (Bulley et al., 2017; McGuire & Kable, 2013), therefore, the appropriate response might be to develop a short time horizon (Becker & Mulligan, 1997; Daly & Wilson, 2005; Pepper & Nettle, 2017) and to adopt strategies such as giving birth, as soon as possible, to the maximum number of offspring (Dickins et al., 2012; Johns et al., 2011; Nettle et al., 2011; Worthman, 2003). In these ecologies, long-term resource allocation may not pay off because there is uncertainty (i.e. the distribution of outcomes has unknown properties such as the mean or SD due to random variation) that the organism will live until late adulthood. Although environmental harshness (risk of mortality-morbidity) and unpredictability (stochastic variation in salient environmental conditions which prevents ex-ante accurate predictions due to factors such as a lack of information or excessive complexity) are
theoretically and empirically dissociable and may have differential effects on several life
traits (Belsky et al., 2012; Brumbach et al., 2009; Ellis et al., 2009), an orientation to
the short-run is by definition predicted by both factors (Ellis et al., 2009; Frankenhuis et al.,
2016; Roff, 1993). In addition, the evidence suggests that the effects of environmental
harshness and unpredictability on life history strategies are additive, not interactive
(Brumbach et al., 2009). We further expand on this point in the Discussion section.
In this vein, the aforementioned models based on Life History Theory predict that Gitanos
will tend to display higher DD rates than their non-Romani neighbors, due to the different
ecologies faced. Moreover, it is expected that individual socio-economic factors such as
current (at adult age) education and income account for some but not all of the difference
because life-history-related behavioral traits such as temporal orientation are thought to be
mainly shaped in earlier stages of development (e.g., Belsky et al., 1991; Griskevicius et al.,
2011; McCullough et al., 2013; Mell et al., 2018). Group differences should indeed explain
a large share of the individual differences, given the shared environmental influences during
development within each group.

2. Methods

2.1. Protocol and participants

Five lab-in-the-field experimental sessions were conducted in five similar semi-rural towns
in Southern Spain (see Espín et al. 2012 for more details). From a total of 160 participants,
nine were excluded from the analyses due to missing information in some of the key variables
of this study. The final sample thus consists of 151 participants (63.6% females). Among
these, 64 are (self-)identified as Gitanos, whereas 87 belong to the majority, non-Romani
population. Average age in our sample was 46.8 (range 17-82) years old. All the socio-
demographic data were gathered in a post-experimental face-to-face interview, where age and years of schooling were obtained as continuous variables, while bins were used for income information (“no income (0€)”, “less than 500€”, “500€ or more but less than 1000€”, and so on; see Table 1).

We did not ask participants directly about their ethnicity. Instead we took advantage of researchers with extensive experience in the field to help us identify potential participants from both ethnic affiliations. In these villages, ethnicity is common knowledge and often verbalized – as was confirmed during the post-experimental interviews.

We have reported all the measures obtained and the experimental conditions that are relevant to the current study. Data exclusions are reported and justified below. The initial sample size (160 observations) was identical to Ramos et al. (2013) and allows us to obtain moderate differences (effect size, \(d=0.45\)) between the two groups with 80% power and \(\alpha=0.05\), accounting for representativeness in the relative sample sizes of the two groups (i.e., Gitanos represent between 1/5 and 2/5 of the towns’ population).

Our procedure excluded two Gitanos from the sample for having missing income information and seven non-Gitanos, three for missing education achievement and four for missing income information. Except for three cases (one Gitano and two non-Gitanos) in which the participant did not know, or did not want to report, the income information, all missing values arise from interviewer’s mistakes (failing to ask one of the questions). The later means that missing values can be considered random so that excluding those nine observations should not produce distortions. An alternative method based on the imputation of missing values to the sample average yields qualitatively similar results (see Text S3 in the Supplementary Materials).
The experimental sessions consisted of 32 participants each. The setting was nearly identical in each of the five towns. The Town Hall provided us with a large room, where we set up the “artefactual” lab consisting of a whiteboard, and 32 chairs and desks. Figure 1 shows one of the five assembled labs. As shown in Figure 1, cardboards were used to prevent visual contact between participants in order to ensure private decisions. Three of the authors plus a group of four assistants supervised all the sessions. The instructions were read aloud always by the same experienced researcher (see Text S1 in the Supplementary Materials).

Figure 1. Representative “artefactual” lab. Location: Deifontes, Granada.

2.2. Delay discounting task and measures
To measure the participants’ DD, we employed a multiple-price-list task (Harrison et al., 2002) with a one-month front-end delay (Espín et al., 2012). Using a decision sheet (see Figure S1 in the Supplementary Materials), the task consisted of 20 decisions in which the participant had to choose between receiving €150 in one month time and receiving a higher amount (increasing from €151.50 to €225 across decisions) in seven months time by marking the preferred option with a cross. These increasing amounts to be received after seven months were also presented in terms of simple interest rates. The lowest amount in the seven-month option (i.e., €151.50) added €1.50 to the €150 of the one-month option, which entails an increase of 1% in six months, that is, an annual simple interest rate of 2%. The highest amount in the seven-month option (i.e., €225) added €75 to the €150 of the one-month option, which entails an increase of 50% in six months, that is, an annual simple interest rate of 100%. All participants were presented with same decisions in the same (ascending) order. The fact that both the sooner-smaller and the later-larger reward were delayed, so that there was no “today” option, allows capturing long-term discounting behavior and alleviates the effect of distrust (about the experimenters actually coming back to the town to pay participants) on decisions. However, as detailed in the Discussion section, the use of this type of task entails some limitations that might influence our results.

In every session, one participant was randomly chosen to receive the real payment (on the specific date) associated with the participant’s choice in one randomly-selected decision. Please refer to the Supplementary Materials (Text S1) for a more detailed explanation of the experimental procedure.

2.3. Delay discounting measures.
In the literature on DD there is considerable debate over which particular functional form better characterizes individuals’ discounting (Andersen et al., 2014; Frederick et al., 2002). The most common measures of DD are based on either exponential (constant-discounting) or hyperbolic (decreasing-discounting) functional forms. For robustness, we test our hypothesis using both characterizations. In particular, we obtained a discounting parameter $K$ for each individual using the following equations:

- For the hyperbolic functional form (henceforth $Hyper-K$)
  \[ V_d = \frac{V_u}{(1 + Kd)} \]

- For the exponential functional form (henceforth $Exp-K$)
  \[ V_d = V_u e^{-Kd} \]

Where $V_d$ stands for the reward's discounted subjective value, $V_u$ refers to its undiscounted value and $d$ is the delay until its receipt (in years). The $K$ parameter is derived from equalizing the discounted value of the sooner-smaller reward to that of the later-larger reward at the individual’s indifference point between both rewards (see next subsection for an explanation of the different indifference points considered in the different analyses). The higher the $K$, the more heavily future rewards are discounted and thus the more short-run oriented the individual is.

The stability and external validity of DD measures have been evaluated in a number of previous studies. The test-retest stability of discount rates has been found to be in the range that is typically obtained for personality traits (Anokhin et al., 2015; Kirby, 2009; Ohmura et al., 2006). While some null results exist (e.g., Eisenstein et al., 2015; Mejía-Cruz et al., 2016; Stojek et al., 2014), evidence abounds that supports the validity of DD measures to predict behaviors with future consequences, such as addictions and drug consumption (Baker et al.,
2003; Bickel & Marsch, 2001; Yi et al., 2010), physical activity and obesity/overweight 
(Chabris et al., 2008; Reimers et al., 2009; Weller et al., 2008), and savings and loan use 
(Meier & Sprenger, 2010, 2012; Sutter et al., 2013).

2.4. Statistical analysis

We first report descriptive statistics for all the variables analyzed, separately for the Gitano 
and majority samples, in Table 1. Zero-order Spearman’s correlations between all the 
variables are presented in Table 2. Since the variables used in these initial analyses are 
categorical and/or arguably not normally distributed, parametric methods such as t-test or 
Pearson’s correlation are not justified, and thus we stick to non-parametric analysis. Although 
for some secondary analyses other approaches such as Fisher’s exact or Mann-Whitney tests 
tend to be more suitable, in the main text we report only correlations (Table 2) for the sake 
of brevity and, when appropriate, refer to the p-values from those other tests, which are 
developed in more detail in Text S2 in the Supplementary Materials.

In Figure 2, we visually compare the DD of Gitanos with that of the majority employing 
different approaches (comparing cumulative distribution functions and subgroups in terms 
of age and income). For all these analyses, we consider that the smallest amount at which an 
individual is willing to wait the six months longer (i.e., seven months instead of one) 
represents her indifference point between the sooner-smaller and the later-larger reward (as 
in Espín et al., 2012).

For the second and main analysis, we estimated individuals’ $K$ parameters using interval 
regressions (Harrison et al., 2002). In this set of regressions, the indifference point of an 
individual is estimated to be in the interval between the later-larger amount offered in the 
decision immediately before the individual switched from the sooner-smaller to the later-
larger reward and that offered in the switching decision (for those individuals who never
switched, the interval is assumed to be open; note that participants were specifically
instructed not to follow multiple-switching, inconsistent patterns, as explained in more detail
in Text S1). The interval regression method, thus, does not force us to assume an arbitrary,
fixed indifference point (for instance, at the midpoint or the upper/lower bound) within each
interval since it is instead estimated from the participants’ choices. This exercise cannot be
done with other estimation methods such as ANOVA, OLS or Tobit. The regression analysis
also allows us to control for key individual variables which could mediate a potential
difference in DD between Gitanos and the majority.

All the analyses were conducted using Stata v12 (StataCorp, Texas, USA). Unless otherwise
stated, reported p-values were calculated from two-tailed tests.

2.5. Data availability

The data and code associated with this research are available at [link].

3. Results

Regarding demographic differences between the Gitanos and majority samples, the former
were younger and more likely to be males (see Table 1; both ps<0.03 according to Mann-
Whitney and Fisher’s exact test, respectively, Text S2). For current SES, we observe that
Gitanos were less likely to have a regular monthly income source, and reported a lower
monthly income (both own income and other household’s income) and a lower number of
years of schooling, compared to the majority (all ps<0.01, see Table 1 and Text S2). These
differences are an indication of the representativeness of our Gitanos and majority samples
but also reflect the necessity of controlling for these variables in a regression analysis.
In panel A of Figure 2, a stochastic dominance approach is used to compare the responses of the two ethnic groups in the DD task. In panels B and C, respectively, we display the mean Hyper-$K$ and Exp-$K$ of the two groups for each age tercile (note that we split age into terciles for visual clarity in the figure as it is the minimal split to observe potential non-linear relationships; all statistical analyses were performed using age as a continuous variable, though). Finally, in panels D and E, we perform the same comparison but now the sample is split into below-median and above-median total household income (given by the combination of own income and other household’s income).
Figure 2. Comparison of DD between the *Gitano* and the majority samples. Stochastic dominance analysis (panel A); mean Hyper-$K$ and Exp-$K$ for each age tercile (panels B and C); mean Hyper-$K$ and Exp-$K$ for below- and above-median total household income (panels D and E).
We observe that, on average, *Gitanos* discount the future more heavily than the majority (mean differences of 0.272 and 0.181 for *Hyper-K* and *Exp-K*, respectively; see Table 1). For both characterizations of $K$, the raw (without controls) difference between *Gitanos* and the majority is significant according to Mann-Whitney test ($p<0.01$, Text S2) and interval regression ($ps<0.01$, Table 3, model 1). Similarly, as shown in panel A of Figure 2, the DD of the majority is stochastically dominated by that of *Gitanos*. More specifically, strict dominance is observed for all values (number of sooner-smaller choices) higher than two.

From Figure 2A we can also see that our DD measure is strongly right-censored, especially for *Gitanos* (48% and 21% of the *Gitano* and majority individuals, respectively, chose the sooner-smaller option in every decision), which implies that reported differences will tend to underestimate the true underlying effect.

However, as mentioned, *Gitanos* differ from the majority according to all the variables which will serve as individual-level controls. More importantly, some of these variables are also correlated with DD, in particular those used as proxies for current SES: income (both one’s own and household’s income) and years of schooling are negatively related with DD, although in some cases the correlation is only marginally significant ($ps<0.07$, Table 2). Therefore, the aforementioned ethnic differences in DD might actually be driven by individual socio-economic factors.

After controlling for these potential individual-level confounds, however, *Gitanos* still display higher discount rates than the majority according to both DD characterizations ($ps<0.03$, models 2-4 in Table 3; see also panels B-E in Figure 2). Comparing model 1 with models 2-4 in Table 3, we observe that the addition of control variables does not substantially reduce the coefficient of ethnicity. Furthermore, among the control variables, only the highest category of own income ($€2000-€3000$) remains significant or marginally significant when
ethnicity is taken into account (ps<0.06); although as can be seen in Table 1 there are no Gitanos in this category, so this result is arguably trivial. Both education and household’s income become non-significant (ps>0.40). Thus, it is the group-level differences that appear to explain a large portion of the individual-level differences, not the opposite. While our interval regressions do not allow us to compare the partial variance explained by each explanatory variable, an approximation using hierarchical OLS regressions (assuming known indifference points as for the previous secondary analyses, see the Statistical Analysis section) yields useful insights. On the one hand, if entered first, ethnicity explains 9.8% and 9.1% of the variance of Hyper-K and Exp-K, respectively (both ps<0.01), and adding current SES (income and education variables) increases R² by 2.6% and 2.8%, respectively. The explanatory power added by current SES is non-significant, however (both ps>0.33). On the other hand, if entered first, current SES explains 7.7% and 7.6% of the variance of Hyper-K and Exp-K, respectively (both ps<0.01), and adding ethnicity increases R² by 4.7% and 4.3%, respectively. The explanatory power added by ethnicity is significant (both ps<0.01).

Finally, another prediction of an adaptationist approach to DD is that age will show a U-shaped relationship with K: both young and old individuals must discount the future more heavily than middle-aged individuals (Becker & Mulligan, 1997; Read & Read, 2004) because external hazards are perceived to be higher at younger ages (i.e., young people do not yet know if their world is risky or safe) whereas the true risk of death increases with age (Sozou & Seymour, 2003). We indeed observe a slight U-shaped relationship between age and K, in particular among Gitanos (see panels B and C in Figure 2), with a minimum K at about 44 yr. according to the regression estimates (see models 2-4 in Table 3), similarly to (Read & Read, 2004). Yet, the coefficients of age and age squared would become only close to significance even using one-tailed hypothesis testing (which is justified if the U-shape
hypothesis is considered directional; ps<0.20 and ps<0.10 for two- and one-tailed tests, respectively).

4. Discussion

These results contribute to the scarce empirical literature on group-level differences in discounting behavior. Our data supports the adaptationist arguments of leading models built upon Life History Theory (e.g., Ellis et al., 2009; Frankenhuis et al., 2016; Kaplan & Gangestad, 2005). That is, participants from the ethnic group which faces harsher and more unpredictable ecological conditions discount the future more heavily even after controlling for the individuals’ current SES. Those adaptationist arguments applied to our results would entail that Gitanos discount the future heavily due to environmental uncontrollable factors which turn a preference for the present to be contextually appropriate, at least at the developmental time when this trait is established. Moreover, current SES loses nearly all its explanatory power once ethnicity is taken into account (although it is true that our current SES measures could not cover the whole spectrum of SES-related variables and there might be not enough variability, especially among Gitanos). This may ultimately imply that some fraction of the previously-reported relationship between socio-economic variables and DD (Harrison et al., 2002; Kirby et al., 2002; Read & Read, 2004; Tanaka et al., 2010) could be driven by unobserved factors related to the ecological conditions under which individuals developed, rather than by the individuals’ current SES.

Recent research shows that individuals from small-scale societies with immediate-return systems display higher DD rates than individuals from agricultural societies in which resource accumulation is more pervasive (Salali & Migliano, 2015). The authors argue that in egalitarian immediate-return economic systems, discounting the future may be a group-
level adaptive strategy to the extent that it prevents resource accumulation and, consequently, the formation of hierarchies which could threat within-group equality (Salali & Migliano, 2015; Woodburn, 1982). More research is required, however, to determine whether the existence of group-level selective pressures is a necessary prerequisite for the emergence of this kind of inter-group behavioral differences.

In sum, further empirical research should systematically assess the extent to which inter-individual differences in DD can be better characterized as inter-group differences. Ours is only a first step in this direction which must be complemented with data from a larger number of ethnic groups before being able to draw firmer conclusions. The study of only two ethnic groups which differ in a number of current and historical ecological factors (such as life expectancy, health and socio-economic status, discrimination and persecution rates) prevents a systematic dissection of the partial effects of each one of these group-level differences on DD. A recent study using survey data from more than 40 countries finds that the proportion of “impatient citizens” (i.e., those who chose the sooner-smaller reward in a single hypothetical survey question) in a country is negatively related to the country’s average life expectancy (this result has been replicated by Lee et al. 2018 using a different approach), and that adding life expectancy to the equation eliminates the negative country-level relationship between impatience and age at first birth (Bulley & Pepper, 2017). The latter results, although not directly addressing causality due to the cross-sectional nature of the data, suggest that it is environmental mortality cues (as proxied by life expectancy) that influence both short-run orientation and early-reproduction decisions.

With the present data, causality cannot be assessed either and many questions remain unanswered. For instance, future research should try to elucidate which part of the inter-ethnic differences in DD might be understood as reflecting group-level (culturally
transmitted) adaptations rather than individual-level adaptations to group-level conditions (Cavalli-Sforza, & Feldman, 1981; Lumsden & Wilson, 1981; McElreath et al., 2003). Life history traits may be acquired through cultural transmission (Boyd & Richerson, 1988; Lumsden & Wilson, 1981). In our case, the historical common experience of discrimination and persecution of the Gitano population, which are nowadays much reduced as compared to past centuries, is an obvious candidate to represent a cultural influence on the Gitanos’ discounting behavior. Only the study of a larger number ethnic groups with varying group-level differences (in terms of both current and historical socio-ecological conditions), however, can effectively tackle this question. Yet, such an exercise would unavoidably lead to loss of experimental control since the inclusion of a larger number of ethnic groups, to the extent that they do not live in the exact same place, implies that many confounding factors are at play, such as geography, natural resource availability, weather, and political regime. Finally, our method to measure DD imposes several limitations that merit consideration. Although we focus on the differences between groups rather than on the exact estimated discount rates of participants, with the type of DD task we use, the elicited discount rates may be confounded by a series of factors. First, note that if Gitanos were less able than the majority to access and exploit the capital market (which seems reasonable), this might translate into higher estimated discount rates which are not related to pure time preference but to the (im)possibility of intertemporal arbitrage (Frederick et al, 2002). Although we consider that the relatively small monetary rewards offered in the task are not treated by subjects as susceptible for market arbitrage, and we also control for a number of income-related variables, whether this factor can explain part of the difference between Gitanos and the majority is an interesting endeavor for future research. Second, another possible confound relates to the concavity of the utility function. Our method assumes that individuals’ utility
functions are approximately linear over the range of stakes involved (this is common in the experimental literature on DD). However, a more concave utility function can be confounded with a higher discount rate (Andersen et al., 2008; Frederick et al, 2002; Lopez-Guzman et al., 2018). In this vein, our results could also be partially explained if *Gitanos* have a more concave utility function compared to the majority. Yet, this would mean that *Gitanos* are more risk averse since individual risk aversion is measured by the concavity of the utility function. Such an argument, while possible, is difficult to sustain given the evidence reviewed earlier (for instance, on incarceration rates).

Third, the preference for sooner-smaller rewards over later-larger ones might be due to uncertainty about the future (Frederick et al, 2002). If any subject feels that the later reward will probably not be delivered then she can take the sooner reward in order to avoid the uncertainty. Therefore, she may appear as impatient while she is not. To alleviate this concern, we used a front-end delay methodology (Harrison et al., 2002) in which both the sooner and the later reward are delayed: the sooner reward is delayed by one month and the later by seven months. Hence, if there is uncertainty/distrust about future payments then both choices will be equally dubious. Note that if the sooner payment is immediate (instead of delayed) – as e.g. in Anokhin et al. (2011), Barkley et al. (2001), Dombrovski et al. (2011), Kirby et al. (2002) – then the respondent may choose it to reduce uncertainty instead of due to pure time preferences. Therefore our results might be explained by uncertainty only if *Gitanos* perceive the future (not the delayed payments in the task per se) as more uncertain than the majority. This is exactly what our paper argues: since the environment of *Gitanos* is harsher and the future is more uncertain for them, they are more focused on the short-run than the majority.
Fourth, a higher expectation of future inflation may lead an individual to prefer sooner-smaller rewards without the influence of time preference, simply because the money is worth less in the future (Frederick et al, 2002). If this confound explains part of our results, it would mean that Gitanos expect higher inflation than non-Gitanos. In principle, we consider this to be counterintuitive since Gitanos should instead be potentially assumed to care less about the possibility of inflation due to their poorer knowledge of economic dynamics – i.e. they should be more, not less, affected by “money illusion”. Even assuming that Gitanos expect higher inflation than non-Gitanos (due to any unobserved differential experience they might have), it is worth noting that the DD differences between the two groups are remarkable. To explain the current results in absence of time preferences, Gitanos should expect a differential inflation >25% than the majority. However, the maximum inflation rate that Spain has experienced in the last 30 years was about 7%, with an average of about 3%. Thus, it sounds sensible to conclude that different expectations of inflation do not crucially drive our results.

Fifth, if someone believes she will be richer in the future, she might associate a lower relative value to the future rewards – and thus look as more impatient - without any true effect of time preference (Frederick et al, 2002). Applied to our results, this would mean that Gitanos expect to be relatively richer in seven months (vs. one month) compared to non-Gitanos. In order to test the validity of this concern, we compared the DD of the two groups only for those individuals who have a regular monthly income source. People with regular income are expected to exhibit more homogeneous beliefs about their future wealth than those individuals with irregular income sources. Thus, if this confound is partially driving our results, we would expect that the DD differences between the two groups would be reduced for the subsample of subjects with regular income. However, among those with regular monthly income (n=58), the difference in estimated exponential discount rate between
Gitanos and the majority is about 0.50 (p<0.01; controlling for demographic variables) while among those with more irregular incomes (n=93) the difference is about 0.30 (p<0.02). Therefore, we conclude that this result does not support the hypothesis of expectations of changing utility. In any case, please note that the gap between the two options is only 6 months, short enough to avoid large changes in expected wealth.

In sum, our results suggest that discounting the future heavily might be a contextually appropriate response under the environmental conditions faced by Gitanos. A preference for the short-run could thus be developed as an adaptive response to uncertain and harsh ecologies, which talks against the view of impatience as dysfunctional, even if it may yield undesirable outcomes such as drug consumption and other unhealthy behaviors. The latter, however, opens the door for reverse or bi-directional causality in the sense that high DD may trigger morbidity and lower life expectancy. One potential source of reverse causality is genetics: if DD is heritable (Anokhin et al., 2011, 2015; Aycinena & Rentschler, 2017; Bevilacqua & Goldman, 2013), a negative relationship between life expectancy and impatience (Bulley & Pepper, 2017; Lee et al., 2018), for instance, might be led by genetic variation rather than life history calibrations (see Zietsch, 2016 for a discussion).³ Regarding the current results, it might seem plausible that genetic differences between Gitanos and non-Gitanos help explain the DD differences. Since inbreeding and endogamy should have increased genetic homogeneity/isolation among Gitanos (Cavalli-Sforza et al., 2004; Kalaydjieva et al. 2001, 2005), it follows that if genetic variation drives behavioral variation, Gitanos’ DD should display lower variance than that of the majority. Yet, variance tests cannot reject the hypothesis that behavioral heterogeneity is the same in the two groups. Indeed, even if Gitanos exhibit slightly lower variance in DD (0.40 vs. 0.42 for Hyper-K and

³ We thank Reviewer 2 for suggesting us this discussion.
0.27 vs. 0.29 for Exp-K), the difference is largely insignificant (both ps>0.55, two-tailed).
Moreover, recall that Gitanos were more likely to choose the sooner-smaller reward in every
decision (48% and 21% of the Gitano and majority individuals, respectively, chose the
sooner-smaller option in every decision; see Figure 2A). This fact, arising from the task
design, arguably increases the relative behavioral homogeneity among Gitanos artificially.
The same variance tests conducted excluding those individuals still do not yield significance
but show that variation is even slightly higher among Gitanos (0.38 vs. 0.34 for Hyper-K and
0.27 vs. 0.25 for Exp-K; both ps>0.44). These results, therefore, do not favor a gene-based
explanation of the between-groups DD differences.
Further research should systematically unpack the relative influences that each one of the
specific environmental factors defining individuals’ living ecologies have on discounting
behavior. In particular, our data indicate that the formation of individuals’ time preferences
might be importantly shaped by group-level social factors such as discrimination and
segregation through their direct impact on environmental harshness and unpredictability.

**Ethics statement**
All participants provided consent prior to participation. Oral informed consent was obtained
because literacy was not a requirement to participate due to the (expected) low educational
level of many participants; only being able to read and write numbers was required to
participate. This study was conducted in accordance with the Declaration of Helsinki for
human research. All participants were treated anonymously by assigning them a numerical
code in accordance with the Spanish Law 15/1999 on Personal Data Protection.

Notes: Number of observations, mean, standard deviation, minimum value and maximum value for each of the variables used in the analyses, separately for the *Gitano* and majority samples. Note that the average educational level of our participants is rather low as compared to the country’s official statistics due to the facts that (i) the experiments were conducted in a semi-rural and low-income area, and (ii) that the participants were older than the average Spanish population (older adults are still nowadays less educated than younger ones in Spain, especially in rural and poor areas; see the strong negative correlation between age and years of schooling in Table 2).

Notes: Interval regression estimates. Model 1 tests the effect of ethnicity on DD without control variables. In model 2, demographic controls are included (Age² refers to Age²/100). Whether the individual has a regular income source and the individual’s own monthly income (omitted category: €0) are also controlled for in model 3. Finally, model 4 also controls for other household’s income (omitted category: €0) and years of schooling. For each model specification, Hyper-K and Exp-
$K$ are the dependent variable in column (a) and (b), respectively. Robust standard errors in parentheses. Pseudo-$R^2$ refers to Cox-Snell’s index. * $p<0.1$, ** $p<0.05$, *** $p<0.01$, two-tailed.
S1. The delay discounting task

For the experiment, we used an adaptation of the intertemporal choice task used by Harrison et al. (2002; see main text). We decided to use a front-end delay procedure to capture long-term discounting behavior and minimize the effect of distrust (in terms of whether the experimenters will effectively come back to the town to pay participants) on individuals’ choices. To do this, we employed a task consisting of 20 categories ranging from 2% to 100% simple annual interest rate ($r$). The procedure was as follows.

Four assistants delivered the delay discounting decision sheet to the participants (each session consisted of 32 individuals, always with the same instructor [PBG] conducting the experiments). As can be seen in Figure S1, the decision sheet contained a table with two main columns (options A and B) and 20 rows. In each row, option A offered €150 to be received one month after the experiment, while option B offered a higher amount to be received seven months after the experiment. In an extra column, the participants could see the interest rate associated with the six-month wait (that is, with choosing option B), which increases across rows from 2% to 100%. Thus, option B in the first row offered €151.50 (i.e. $r = 0.02$) and option B in the twentieth row offered €225 ($r = 1$). The participants had to choose between option A and B in each of the 20 rows by marking with a cross on the corresponding column.

In order to avoid mistakes and, more specifically, inconsistent choices – a frequent problem with multiple-price-list tasks, where multiple switching patterns are often observed, even among university students —, the instructor conducted the task row by row. Subjects were asked, scenario by scenario, to choose between A and B. Moreover, they were advised that once option B was reached they should stay at that point, given that once B has been already chosen it makes no sense to switch to option A again in the next row. Given the (expected) low educational level of a non-negligible proportion of our
participants (see Table 1 in the main text), we believe that this systematic procedure importantly reduced the number of mistakes. Since inconsistent choices impede the estimation of an individual’s discount rate, we thus reduced a potentially high number of missing observations to zero.

The participants were told that because of financial constraints only one, randomly selected individual per session would be paid for this part of the experiment. Once the decision sheets were collected, the “winner” and the “prize” (row) were randomly selected by picking numbered balls from an opaque bag in front of the participants. The average earnings of the five selected participants were €166.50. One member of the team [AME] phoned each of them in order to arrange a meeting for payment after one or seven months depending on the option chosen by the participant in the randomly selected row. This was common knowledge among participants when making their decisions. Since both options in the task were delayed (front-end delay), our design avoids the problem of different transaction costs between options – including different levels of trust in getting actually paid.

S2. Robustness checks for secondary analyses

In this section, we complement the statistical analysis reported in the main text based on Spearman correlations (Table 2). In particular, we check the robustness of those analyses which include at least one binary variable to more appropriate statistical tests (i.e. either Mann-Whitney test or Fisher’s exact test in the case of two binary variables; two-tailed).

According to Mann-Whitney test,

- compared to a non-**Gitano**, the probability that a **Gitano**: chooses the sooner-smaller reward more often in the DD task is 68.2% (p<0.001); is older is 27.6% (p<0.001); reports a higher personal income is 37.9% (p=0.008); reports a higher (other) household’s income is 32.6% (p<0.001); reports a higher number of years of schooling is 27.1% (p<0.001).

- compared to a female, the probability that a male: chooses the sooner-smaller reward more often in the DD task is 50.2% (p=0.962); is older is 46.3% (p=0.451); reports a higher personal income is 65.9% (p<0.001); reports a higher (other) household’s income is 40.0% (p=0.034); reports a higher number of years of schooling is 53.0% (p=0.509).

- compared to someone without regular income, the probability that a participant with regular income: chooses the sooner-smaller reward more often in the DD task is 43.5% (p=0.171); is older is 69.7% (p<0.001); reports a higher personal income is 87.9% (p<0.001); reports a higher (other) household’s income is 42.5% (p=0.110); reports a higher number of years of schooling is 52.1% (p=0.636).

According to Fisher’s exact test,

- compared to non-**Gitanos**, **Gitanos** are 18.2% more likely to be male (46.9% vs. 28.7%; p=0.027) and 23.3% less likely to report a regular income (25.0% vs. 48.3%; p=0.004).

- compared to females, males are 21.0% more likely to be **Gitano** (54.5% vs. 35.4%; p=0.027) and 22.5% more likely to report a regular income (52.7% vs. 30.2%; p=0.009).
• compared to those without regular income, participants with regular income are 24.0% less likely to be Gitano (27.6% vs. 51.6%; p=0.004) and 22.0% more likely to be male (50.0% vs. 28.0%; p=0.009)

S3. Robustness checks for the treatment of missing values

Table S1 replicates the set of regressions presented in Table 3 in the main text but replacing the nine missing values with the sample average of the variable in each case.
