Abstract

Purpose: This study compared the associations between optimum power loads and 1-repetition maximum (1RM) values (assessed in half-squat [HS] and jump squat [JS] exercises) and multiple performance measures in elite athletes. **Methods:** Sixty-one elite athletes (fifteen Olympians) from four different sports (track and field [sprinters and jumpers], rugby sevens, bobsled, and soccer) performed squat and countermovement jumps, HS exercise (for assessing 1RM), HS and JS exercises (for assessing bar-power output), and sprint tests (60-m for sprinters and jumpers and 40-m for the other athletes). Pearson's product moment correlation test was used to determine relationships between 1RM and bar-power outputs with vertical jumps and sprint times in both exercises. **Results:** Overall, both measurements were <mark>moderately to near perfectly related to speed performance</mark> (*r* values varying from -0.35 to -0.69 for correlations between 1RM and sprint times, and from -0.36 to -0.91 for correlations between bar-power outputs and sprint times; *P*< 0.05). However, on average, the magnitude of these correlations was stronger for power-related variables, and <mark>only the bar-power outputs were significantly related to vertical jump height</mark>. **Conclusions:** The bar-power outputs were more strongly associated with sprint-speed and power performance than the 1RM measures. Therefore, coaches and researchers can use the bar-power approach for athlete testing and monitoring. Due to the strong correlations presented, it is possible to infer that meaningful variations in bar-power production may also represent substantial changes in actual sport performance.

Keywords: maximum strength, optimal load, elite athletes, muscle power, bar-velocity.

Introduction

Maximum dynamic strength assessments, also called one-repetition maximum (1RM) tests, are widely used by coaches and researchers to both evaluate neuromuscular performance and determine training loads.[1] The prescription of strength-power training is usually based on different percentages of 1RM, according to the objectives and needs of a given athlete or sport discipline.[1, 2] For example, programs designed to develop maximum strength capacity tend to adopt loading ranges varying between 80 and 100% 1RM; whereas programs focused on developing muscle power normally prioritize the use of exercises performed with light to moderate loads (e.g., 30 to 45% 1RM).[3-5] Thus, independent of their resistance training goals, athletes are often required to perform 1RM tests.

Due to the inherent difficulties in applying 1RM tests[6-8] (and thus monitoring the resistance-training load), velocity-based training (VBT)[9, 10] has emerged as a practical and advantageous alternative to control resistance training intensity.[11, 12] Indeed, the strong relationship between force and velocity enable practitioners to rapidly estimate relative load (i.e., % 1RM), by simply monitoring movement velocity.[11] Several investigations have provided useful information on VBT, reporting reference data which can be precisely used to monitor loading intensity in different exercises.[10, 11] Nevertheless, this approach normally correlates movement velocities with standard 1RM measures,[13, 14] compromising its applicability as a novel training strategy. Furthermore, recent studies have brought into question the theoretical concepts behind "maximum dynamic strength" assessments, which (in essence) represent only the higher mass that an athlete can move during a maximum-effort resistance exercise.[15, 16] For these authors, the fact that this scalar measure (i.e., mass) does not simultaneously reflect the force and velocity applied by the athlete against an external resistance could hamper its use in high-performance

76 sport, where time and velocity play a critical role in determining the effectiveness of force

77 application.[15]

78   With this in mind, more recently, the use of the "optimum power load" (i.e., load

79 able to maximize power production) has been proposed in athletes' training programs.[16,]

80 [17] Briefly, instead of using reference loads based solely on scalar measures, coaches can

81 adopt a training strategy which considers at the same time the force and velocity applied

82 to the barbell, thus optimizing the power production in this external implement. This load

83 is usually determined in a progressive load test, performed until a decrease in subject's

84 power output is observed.[16, 17] Nonetheless, it appears that these optimized loads always

85 occur at a narrow range of bar-velocities,[17, 18] which strongly facilitates resistance training

86 monitoring and prescription. Based on these ranges, for example, coaches can increase or

87 decrease the load magnitude as soon as the subject leaves the target (velocity) zone.[17, 18]

88 Importantly, it has been shown that training within optimum power zones may be an

89 effective way to improve strength and power abilities at both ends of the force-velocity

90 curve (i.e., low-force, high-velocity portion; and high-force, low-velocity portion).[5, 8]

91 From these findings, it may be inferred that numerous sport disciplines could benefit from

92 using this alternative resistance training scheme rather than more traditional 1RM-based

93 methods.

94   To examine the relationships between this specific range of loads and multiple

95 performance measures in elite athletes from different sports is an important first step in

96 exploring the usefulness and effectiveness of this novel approach. Accordingly,

97 comparing the magnitude of these respective correlations with the magnitude of more

98 established relationships (e.g., correlations between 1RM and performance measures)[19,]

99 [20] could enable practitioners and researchers to better select appropriate training strategies

100 for their athletes. Thus, the aims of the present study were to: (1) analyze the correlations

between bar-power outputs (under optimum loading conditions) and 1RM values (assessed in half-squat [HS] and jump squat [JS] exercises), and multiple performance measures in elite athletes from a range of sport disciplines; and (2) assess the sensitivity and specificity of the bar-power approach for athlete testing and monitoring.

Methods

Subjects

Sixty-one elite athletes from four different sports (14 track & field sprinters and jumpers: 23.9 ± 5.7 years, 66.1 ± 8.7 kg, 176.6 ± 7.8 cm; 18 rugby sevens players: 25.2 ± 3.1 years, 87.9 ± 7.8 kg, 181.5 ± 7.2 cm; 8 bobsled athletes: 28.7 ± 6.5 years, 89.0 ± 9.6 kg, 181.9 ± 9.7 cm; and 21 professional soccer players: 24.8 ± 4.5 years, 66.9 ± 7.6 kg, 176.0 ± 8.5 cm) participated in this study. All participants had at least five years of resistance training experience and, due to their professional training routine, performed a minimum of three and a maximum of five strength-power training sessions per week. The sample comprised 15 athletes who participated in the previous Summer and Winter Olympic Games (10 in Rio de Janeiro 2016 and 5 in PyeongChang 2018). The other athletes were part of the Brazilian National Teams, competing at national and international levels. The professional soccer players participated in the first division of the *"Paulista Championship"*, the most important Brazilian State Championship. Before participating in the study, athletes signed an informed consent form. The study was approved by the Anhanguera-Bandeirante University Ethics Committee (registration number 926.260).

Study Design

125   The athletes involved in this study were assessed during the competitive phase of

126   the season and were well familiarized with testing procedures. Physical tests were

127   performed on two consecutive days in the following order: Day 1) squat jumps (SJ) and

128   countermovement jumps (CMJ) and 1RM in the HS exercise; Day 2) assessment of the

129   maximum power outputs in the HS and JS exercises and a sprint test. After the first day,

130   athletes rested until the next day of assessments. During this period, they were instructed

131   to maintain their nutritional and sleep habits and to arrive at the sports laboratory in a

132   fasted state for at least 2-h, avoiding alcohol and caffeine consumption for at least 48-h

133   before the tests. A standardized warm-up was performed before the tests comprising light

134   to moderate self-selected runs for 5-min, and prior to maximal tests sub-maximal attempts

135   at each test were also performed. Between each test, a 15-min rest interval was

136   implemented to explain the next procedures and adjust the testing devices.

137

138   *Testing procedures*

139   The SJ and CMJ were performed on a validated contact-mat (Elite Jump, S2

140   sports, Brazil)[21] with the hands on the hips. Five attempts for each jump were allowed

141   and the highest jump of each mode was retained. A 1RM test in the HS exercise was

142   performed on a Smith-machine device (Hammer Strength Equipment, Rosemont, USA)

143   following the standard procedures described elsewhere (Figure 1).[6] Barbell-mean, mean

144   propulsive, and peak power outputs (MP, MPP, and PP, respectively) were assessed in

145   the HS and JS exercises on the Smith-machine using a linear encoder (T-Force, Dynamic

146   Measurement System; Ergotech Consulting, Murcia, Spain), as previously described

147   (Figure 2).[17] Briefly, to determine the optimal power load, the test started at a load

148   corresponding to 40% of the athlete's body mass. Then, a load of 10% of body mass was

149   gradually added in each set, until a clear decrement in the bar power was observed.[17] The

150 <mark>loads corresponding to the highest power outputs in both exercises were retained for</mark>

151 <mark>analysis.[17, 18] Both 1RM and power outputs</mark> were normalized to the athletes' body-mass

152 (BM). For the sprint test, sprinters and jumpers performed a 60-m sprint test, whereas the

153 other athletes sprinted over a total distance of 40-m. Five pairs of photocells (Smart-

154 Speed, Fusion Equipment, Brisbane, AUS) were positioned at distances of zero, 10-, 20-

155 , 30-, and 40-m along the sprinting course, and an additional pair was placed at 60-m to

156 assess sprinters and jumpers. Athletes performed two sprints and the best attempt was

157 retained. <mark>All tests used herein presented high levels of reliability and consistency (ICC ></mark>

158 <mark>0.92 and CV <4%, for all performance measures).[22]</mark>

159

160   *****INSERT FIGURE 1 HERE*****

161

162   *****INSERT FIGURE 2 HERE*****

163

164 *Statistical analysis*

165   Data normality was confirmed via the Kolmogorov-Smirnov test. The Pearson's

166 product moment correlation test was used to determine the relationships between 1RM

167 and power outputs in both exercises with vertical jumps and sprinting velocities.

168 Correlation values were qualitatively assessed using the criteria established by Hopkins

169 et al.[22], as follows: <0.1, trivial; 0.1-0.3, small; 0.3-0.5, moderate; 0.5-0.7, large; 0.7-0.9,

170 very large; >0.9 nearly perfect. The level of significance was set at $P < 0.05$.

171

172 **Results**

173   Descriptive data of the physical tests performed are presented in table 1. Table 2

174 shows the correlations between 1RM and power outputs in the HS and JS exercises with

175 the vertical jumps and 60-m sprinting times. For all power outputs significant correlations

176 were observed between the SJ and CMJ heights (varying between 0.58 and 0.82; $P < 0.05$),

177 while no significant correlations were found between 1RM and the vertical jumps. The

178 highest correlation values were observed between the different power outputs and 60-m

179 sprint time (varying between -0.80 and -0.91; $P < 0.05$), while the correlation between the

180 1RM with the same sprint distance was -0.63 ($P < 0.05$).

185

186 **Discussion**

187 This study examined the relationships between 1RM values and maximum power

188 outputs with multiple performance measures in elite athletes from different sports.

189 Overall, both measurements were significantly related to speed-power variables (with the

190 exception of SJ, CMJ and time 5-m, and 1RM). However, on average, the magnitude of

191 these correlations was stronger for power-related variables, indicating that these outputs

192 may be more strongly associated with sport-performance than 1RM loads.

193 The association between 1RM measures and performance has been extensively

194 described in many studies and within a recent review.[20] Wisloff et al.[23] reported

195 significant correlations between half-squat 1RM and sprint and jump performance (from

196 0.71 to 0.94) in professional soccer players. Similarly, McBride et al. (2009) found

197 significant relationships among a series of speed-tests (5, 10, and 40-yard) and back-squat

198 1RM, emphasizing the importance of normalizing 1RM values by the athletes' BM (as

199 relative values) to strengthen the associations between strength and performance

200   measures.[19] In the present study, both 1RM and power outputs were expressed in relative

201   values, which likely contributed to increase the magnitude of the correlations observed

202   (Table 2). Nonetheless, as previously mentioned, these values were higher for power-

203   related variables and, notably, only these outputs were significantly associated with

204   vertical jump performance.

205   Requena et al.[24] reported similar results with well-trained sprinters, not finding

206   significant relationships between relative measures of squat 1RM and CMJ height. In

207   contrast, relative power production (in both squat and JS exercises) were found to be

208   moderately related to jump ability and maximal speed over different distances (from 20-

209   to 80-m). Accordingly, Loturco et al.[25] showed that both the MPP and the magnitude of

210   the load lifted at the optimum zone are highly correlated to sprint and jump capacities (r

211   ~ 0.80) in professional sprinters. These data are very similar to those described herein,

212   confirming the usefulness of the bar-power approach in assessing athletic performance,

213   especially in elite athletes. The opportunity to use ranges of loads which optimize the

214   force and velocity applied to the barbell at the same time[15, 26] (instead of only considering

215   the maximum mass moved during a maximum effort [i.e., 1RM]) may better reflect the

216   abilities required in sport-tasks, where athletes are frequently required to move substantial

217   amounts of loads at high speeds (e.g., the BM during a vertical jump or maximal

218   sprints).[25, 27, 28] Although this mechanical parameter does not represent "total power of

219   the system" (i.e., system-power)[15, 16], the bar-power output can be used not only to

220   monitor strength and power capacities, but also to discriminate athletes with different

221   performance levels and training backgrounds.[29]

222   We recognize that the 1RM measurement is widely used to prescribe and control

223   training intensity, and there are several studies confirming its efficacy for such purposes.[1,

224   2, 13] Nevertheless, it is worth noting that, in terms of assessing athletes' performance, the

225 relationship with specific physical capabilities (e.g., jumping and sprinting) is a relevant

226 criterion for test selection.[19, 23, 25] Furthermore, there are potential risks involved in 1RM

227 testing,[6-8] which compromises its frequent use in competitive sports, where the constant

228 evaluation of physical performance is of fundamental importance. More importantly,

229 there is a significant limitation in considering a given scalar variable (i.e., mass) as a

230 "strength measurement".[15, 26] In this context, it is critical to emphasize that the ability to

231 efficiently accelerate relative loads (and thus reach higher movement velocities) is a

232 selective factor in different sport disciplines.[12, 25, 30, 31] The finding that the bar-power

233 output is more strongly associated with sport-performance than 1RM measures indicates

234 that this novel and alternative method might be an effective way to assess elite athletes.

235 Due to the high levels of precision and consistency presented by all power variables,

236 based on their preferences and possibilities (i.e., device features), practitioners can use

237 MP, MPP, or PP to estimate and define the optimum power zones, in both JS and HS

238 exercises.

239

240 **Practical Applications**

241   Frequent monitoring of athletes' performance is essential in professional sports,

242 serving as a basis for adjusting training loads and methods, and evaluating individual

243 progress. Therefore, the use of applied, safe, and timesaving assessment tools becomes

244 crucial for the development of better and more effective training programs. The bar-power

245 approach is a practical training and testing strategy, which has been shown to be closely

246 related to actual performance[25, 30, 31] and produce significant improvements in physical

247 abilities at both ends of the force-velocity curve.[5, 8] In this study, we demonstrated that the

248 bar-power outputs are more strongly associated with speed and power performances in

249 elite athletes than 1RM measurements. With this in mind, coaches and researchers are

250   encouraged to assess the power production directly on the barbell to evaluate the strength-

251   power performance of their athletes. Despite the cross-sectional nature of our data, due to

252   the <mark>large</mark> correlations presented here, it is possible to infer that meaningful variations in

253   bar-power production may also represent substantial changes in athletic performance.

254   Further studies should be conducted to test the relationships between bar-power output

255   and alternative performance measures (e.g., repeated-sprint ability) and sport-tasks (e.g.,

256   change of direction tasks).

257

Conclusions

258

259   The bar-power approach is an effective testing strategy, which can be quickly and

260   easily implemented to evaluate athletes from different sports. The bar-power output

261   collected at the optimum power zone is closely related to athletic performance.
