Abstract—This paper considers data exchange between two terminals in a nonregenerative two-way relay network. We first propose two efficient channel quality indicator (CQI) reporting schemes based on XOR and superposition coding for single-relay networks. These schemes allow two terminals to simultaneously estimate the CQI of the distant link without incurring additional overhead. In addition, the transmission time for CQI feedback is reduced by half while the loss of performance is negligible. Upper and lower bounds of the mean square error (MSE) of the estimated CQI are derived to analyze various effects on the performance of the proposed schemes. We then extend our MSE analysis to multi-relay networks where a low-complexity relay selection scheme is proposed based on the derived bounds. Simulation results show that, in comparison with conventional methods, this suboptimal bound-based scheme achieves satisfactory performance while reducing the complexity at least three times in case of large number of relays.

I. INTRODUCTION

Recently, network coding (NC) [1] has been proposed to increase the system throughput in lossless networks. The principle of NC is that intermediate nodes are allowed to mix signals received from multiple links for subsequent transmissions, e.g., using XOR operator to mix two signals from two terminals. Specifically, several studies have been dedicated to investigating the application of NC to two-way single-relay network (TWSRN) [2]–[4].

In this paper, we consider a TWSRN model that includes two terminal nodes \( T_1, T_2 \), and a relay node \( R \). It is assumed that the relay works under nonregenerative protocol and there is no direct link between the terminals. In general, in order to help one terminal node decode the data sent by the other, the channel state information (CSI) of the terminal-relay links should be feedbacked to both terminal nodes. Common mechanisms for CSI feedback are via channel quality indicator (CQI) reporting [5]. Recently, a hierarchically modulated NC scheme has been proposed for asymmetric TWSRNs in which hierarchical modulations are applied at two source nodes based on the channel quality [6]. This scheme works under the assumption that the CQI information is known at all nodes. The above reasons motivate us to investigate the CQI reporting mechanism for TWSRNs where each terminal node is required to know the CQI of the distant terminal-relay link.

Most of recent work investigated CQI reporting or feedback in one-way single-relay networks only for various applications e.g., adaptive non-orthogonal cooperation [7] and adaptive utilisation of time-varying channels [8]. Extending these CQI feedback schemes to TWSRNs obviously results in doubling the signaling overhead and requiring two time slots at each relay node to forward the overhead to both terminal nodes. These drawbacks inspire us to propose a new efficient CQI reporting scheme for NC-based TWSRNs so as to reduce the number of transmissions at \( R \) as well as avoid the additional overhead. The NC is performed at \( R \) using either bitwise XOR or symbol-level superposition coding where the estimated CQIs of the two links \( T_1 - R \) and \( T_2 - R \) are combined to enable \( T_1 \) and \( T_2 \) to simultaneously estimate the CQI of the links \( T_2 - R \) and \( T_1 - R \), respectively. The novelty of our proposed CQI reporting scheme is that it conveys the CQIs of one terminal-relay channel to the other terminal at no additional cost in terms of bandwidth or energy. Extending to an \( N \)-relay network, it can be seen that \( N \) signalling overheads and \( N \) transmission time slots are reduced when compared with the conventional scheme. Thus, the system throughput is considerably improved, especially when \( N \) is large. Besides the advantage of our proposed scheme in improving system throughput, the other major contributions of our paper are the analysis of mean square error (MSE) of the estimated CQI and the subsequently proposed bound-based relay selection scheme, which will be described next.

Our second contribution is the derivation of the upper and lower bounds of MSE of estimated CQI in the proposed scheme over Rayleigh flat fading channel, which, to the best of our knowledge, has not been achieved before. The bounds are shown to be tight and reflect well the behaviour of the numerical MSE. It is also shown that the loss of performance and the increase of complexity of our proposed scheme are negligible compared with conventional schemes. For asymmetric broadcast channels, a better performance can be achieved with superposition coding.

Finally, we extend our proposed scheme to the case of two-way multi-relay networks (TWMRNs). Since the data exchange between two terminals can be assisted by all available relay nodes, opportunistic relay selection (RS) should be considered [4], where the best relay is chosen based on the sum of bit error rate or sum-rate. In this paper, we investigate a system where CQI is required at the transmitter and therefore
CQI reporting is a crucial performance metric for the system. This motivates us to design an efficient opportunistic RS scheme where the best relay is searched based on the sum of MSE (sum-MSE). The RS is realised by a scheduler of a coordinator node in a centralized manner, i.e., the coordinator selects the best relay based on the sum-MSE feedbacked by the relays through specific channels. Furthermore, the high complexity of relay searching in optimal schemes motivates us to propose a suboptimal bound-based relay selection scheme where the searching process will stop whenever the sum-MSE of any relay is smaller than the pre-determined upper bound. It is observed that the resulting complexity is reduced by at least three times compared with conventional selection schemes if the number of relays is sufficiently large.

II. SYSTEM MODEL

Let us consider a typical TWSRN where the data exchange between two terminals $T_1$ and $T_2$ is assisted by a relay $R$. It is assumed that there is no direct link between $T_1$ and $T_2$ due to power limit in each node. We focus on Rayleigh flat fading channel where channel coefficients of $T_1 \rightarrow R$ and $T_2 \rightarrow R$ links are given by $h_{T_1R}$ and $h_{T_2R}$, respectively. We assume that Time-Division Duplex (TDD) is employed and all transmissions are carried out over the same frequency band. Each channel is assumed to be reciprocal (i.e., $h_{T_1R} = h_{T_2R} = h_1$ and $h_{T_2R} = h_{T_1R} = h_2$) and assumed to change every data frame, and thus the CQI reporting should be carried out every time. Pilot signals are used to initially estimate the link quality of all channels (i.e., instantaneous signal-to-noise ratio (SNR) at the receiver).

It is noteworthy that for various signal processing mechanisms in TWSRNs such as data detection or adaptive modulation [6], each terminal node $T_i$ requires the channel quality information of not only its associated link $T_i \rightarrow R$ but also that of the distant link $T_j \rightarrow R$, $j \neq i$. In order to reduce the amount of feedback information, the value of channel quality, SNR, should be quantized into a finite bit sequence called CQI with different levels. The CQI reporting in TWSRN can be divided into two phases as follows:

- First phase: $T_i, i = 1, 2$, and $R$ transmit pilot signals to each other to estimate the CQI of the associated link $T_i \rightarrow R$.
- Second phase: $R$ helps $T_i$ estimate the CQI of the distant link $T_j \rightarrow R, j = 1, 2, j \neq i$, which cannot be directly obtained at $T_i$ since there is no direct link available between $T_i$ and $T_j$.

We observe that the CQI estimation in the first phase can straightforwardly follow conventional pilot-based approaches. We therefore focus on the CQI reporting in the second phase. Conventionally, a double amount of signaling overhead should be required at $R$ to consecutively forward the CQIs of the links $T_1 \rightarrow R$ and $T_2 \rightarrow R$ to $T_1$ and $T_2$, respectively, in two time slots. This considerably reduces the network throughput. Therefore, we propose a new efficient CQI reporting scheme based on NC to eliminate the additional overhead and reduce the number of time slots required. By using NC, $R$ can combine the estimated CQIs of two links $T_1 \rightarrow R$ and $T_2 \rightarrow R$ before broadcasting it to allow each terminal $T_i$ to simultaneously estimate the CQI of the distant link $T_j \rightarrow R$ ($j \neq i$).

Let $\gamma_i$ and $\rho_i$ denote the SNR and CQI, respectively, of link $h_i$ ($i = 1, 2$). Assume that $\rho_i \in C_i$ where $C_i$ is the set of all possible CQI levels of link $h_i$. Let $Q_i$ denote the cardinality of $C_i$. Thus, it requires $L_i = \lceil \log_2 Q_i \rceil$ bits to represent a $\rho_i$ level, where $\lceil \cdot \rceil$ denotes the ceiling function of a real number. The lists of $\rho_1$ and $\rho_2$ levels are assumed to be available at $R$, $T_1$, and $T_2$. Practically, there are multiple ways to map SNR to CQI [9]. One of the common ways is that CQI can be approximated by a linear function of SNR as follows

$$\rho_i = \left[a\gamma_i + b\right],$$

where $a$ and $b$ are the constants and $\gamma_i$ is calculated in dB. Assume that the range of SNR for CQI mapping is from 0 to $\gamma_{mdB}$ [dB], where $\gamma_{mdB}$ is positive and measured in dB.

Following the above approach, we divide the range $[0 : \gamma_{mdB}]$ into $Q_i$ levels (1, 2, ..., $Q_i$) by setting $a = Q_i/\gamma_{mdB}$ and $b = 0$. As a result, we can obtain $\rho_i$ as

$$\rho_i = \left[\frac{Q_i}{\gamma_{mdB}}\gamma_i\right] = \left[\frac{10Q_i \log_{10} \gamma_i}{\gamma_{mdB}}\right].$$

Let $\rho_{i,T}$ and $\rho_{i,R}$ denote the estimated values of $\rho_i$ at $T_i$ and $R$, respectively, in the first phase. It can be seen that $\rho_{i,T}, \rho_{i,R} \in C_i$. We next introduce our proposed CQI reporting schemes for TWSRNs in the second phase.

III. PROPOSED CQI REPORTING SCHEMES FOR TWSRN

Once two estimated CQIs $\rho_{1,R}$ and $\rho_{2,R}$ are available, $R$ can combine them using either bit-level XOR or symbol-level superposition as follows:

**Scheme A – Bit-level XOR**

The bit sequences of $\rho_{1,R}$ and $\rho_{2,R}$ are XORed together as

$$b^{(A)} = b^{(A)}_{\rho_{1,R}} \oplus b^{(A)}_{\rho_{2,R}}.$$

where $\oplus$ denotes the bitwise XOR operator and $b^{(A)}$ is defined as in (3). Let $\rho_{i,T}$ and $\rho_{i,R} \in C_i$. We next introduce our proposed CQI reporting schemes for TWSRN in the second phase.

**Scheme B – Symbol-level superposition**

The bit sequences $b^{(A)}_{\rho_{1,R}}$ and $b^{(A)}_{\rho_{2,R}}$ are encoded into baseband signal sequences $b^{(M)}_{\rho_{1,R}}$ and $b^{(M)}_{\rho_{2,R}}$, respectively. Then, they are superimposed together as

$$b^{(B)} = \sqrt{\theta_{p_1}} b^{(B)}_{\rho_{1,R}} + \sqrt{\theta_{p_2}} b^{(B)}_{\rho_{2,R}},$$

where $\theta_{p_1}$ and $\theta_{p_2}$ are power allocation coefficients such that $\theta_{p_1} + \theta_{p_2} = 1$ and optimised as in [10].

For the CQI estimation at $T_1$ and $T_2$, $R$ then broadcasts $b^{(M)}$, $M \in \{A, B\}$, to $T_1$ and $T_2$. The received signal at $T_i, i = 1, 2$, can be written by

$$y_i^{(M)} = \sqrt{P_R} h_i x^{(M)} + n_i,$$
where $P_R$ is the power level for the pilot signal of $\mathcal{R}$, $\mathbf{x}^{(M)}$ is the modulated version of $\mathbf{b}^{(M)}$, and $\mathbf{n}$ is the white Gaussian noise vector with each entry having zero mean and variance of $\sigma_n^2$.

At $\mathcal{T}_i$, $i = 1, 2$, it is necessary to estimate $\rho_{j,\mathcal{R}}$, $j \neq i$, of the distant link $\mathcal{T}_j - \mathcal{R}$. Based on the estimated CQI of the link $\mathcal{T}_i - \mathcal{R}$ at $\mathcal{T}_i$ (i.e., $\rho_{i,\mathcal{T}}$) in the first phase, $\mathcal{T}_i$ can create a list of all possible NC-based combinations of $\rho_{i,\mathcal{T}}$ and $\rho_j$ using either scheme A or B as follows

**Scheme A**

\[
b^{(A)}_{\rho_j} = b_{\rho_{j,\mathcal{T}}} \oplus b_{\rho_j},
\]

where $b_{\rho_{j,\mathcal{T}}}$ and $b_{\rho_j}$ denote the bit-level formats of $\rho_{i,\mathcal{T}}$ and $\rho_j$, respectively.

**Scheme B**

\[
b^{(B)}_{\rho_j} = \sqrt{\theta_{\rho_j}} b'_{\rho_{j,\mathcal{T}}} + \sqrt{\theta_{\rho_j}} b'_{\rho_j},
\]

where $b'_{\rho_{j,\mathcal{T}}}$ and $b'_{\rho_j}$ denote the encoded baseband signal sequences of $b_{\rho_{j,\mathcal{T}}}$ and $b_{\rho_j}$, respectively.

Note that $\rho_j \in \mathcal{C}_j$ and therefore there are $Q_j$ possible candidates of $b_{\rho_j}$. $\mathcal{T}_i$ then compares the received signal $\mathbf{y}_i^{(M)}$, $M \in \{A, B\}$, given in (5) with all possible $b_{\rho_j}$’s in order to choose the matched $b_{\rho_j}$. Correspondingly, the matched $\rho_j \in \mathcal{C}_j$ can be found. This matched $\rho_j$ is the estimated value of $\rho_{j,\mathcal{R}}$, which is denoted by $\hat{\rho}_{j,\mathcal{R}}$. We observe that finding $\hat{\rho}_{j,\mathcal{R}}$ can be carried out by using an exhaustive search method, where the correlation-based decision is based on the received signal $\mathbf{y}_i^{(M)}$ and the NC-based combination sample $b^{(M)}_{\rho_j}$. This correlation-based decision is represented by the following correlation value:

\[
\phi^{(M)}_{\rho_j} = \sum_{l=1}^{L_m} \mathbf{y}_i^{(M)}[l] \mathbf{y}_{\rho_j}^{(M)}[l]^* / |\mathbf{y}_i^{(M)}[l]|^2,
\]

where $\mathbf{x}_{\rho_j}^{(M)}$ denotes the modulated version of $b^{(M)}_{\rho_j}$. Substituting (5) into (8), we obtain as [11]

\[
\phi^{(M)}_{\rho_j} = \begin{cases} \sqrt{P_R h_1 L_m + \sqrt{L_m} \sigma_1 N_{\rho_j}}, & \text{if } \rho_{i,\mathcal{R}} = \rho_{i,\mathcal{T}} \text{ and } \rho_j = \rho_{j,\mathcal{R}}, \\ \sqrt{P_R h_1 \left( \sqrt{\frac{L_m}{\omega_1}} \omega_1 + \sqrt{\frac{L_m}{\omega_2}} \omega_2 \right) + L_m \sigma_1 N_{\rho_j}}, & \text{otherwise}, \end{cases}
\]

where $\omega_1$ and $\omega_2$ are independent Gaussian random numbers with zero mean and unit variance, and $N_{\rho_j}$ is the independent complex-valued random number [11]. It can be seen that $L_m$ is almost surely greater than $(\omega_1 \sqrt{L_m/2} + \omega_2 \sqrt{-L_m/2})$ when $L_m \geq 2$. Therefore, we can conclude that $\phi^{(M)}_{\rho_j}$ is almost surely upper bounded by $(\sqrt{P_R h_1 L_m + \sqrt{L_m} \sigma_1 N_{\rho_j}})$ when $\rho_{i,\mathcal{R}} = \rho_{i,\mathcal{T}}$ and $\rho_j = \rho_{j,\mathcal{R}}$, i.e., the estimated $\rho_i$ and $\rho_j$ at $\mathcal{R}$ should be equal to the estimated $\rho_i$ and the required $\rho_j$ at $\mathcal{T}_i$, respectively.

Thus, the estimated value of $\rho_{j,R}$ is chosen from $\mathcal{C}_j$ to maximize $\phi^{(M)}_{\rho_j}$ as follows

\[
\hat{\rho}_{j,\mathcal{R}} = \arg \max_{\rho_j \in \mathcal{C}_j} \phi^{(M)}_{\rho_j}.
\]

Note that the estimation of $\rho_{2,\mathcal{R}}$ at $\mathcal{T}_1$ and the estimation of $\rho_{1,\mathcal{R}}$ at $\mathcal{T}_2$ are carried out simultaneously.

**Remark 1.** The required condition $\rho_{i,\mathcal{R}} = \rho_{i,\mathcal{T}}$ in order to maximize $\phi^{(M)}_{\rho_j}$ causes a loss in the performance of our proposed scheme when compared with the conventional scheme in terms of the MSE of the estimated $\rho_{j,\mathcal{R}}$ at $\mathcal{T}_i$. This condition may not be achieved due to the imperfect estimation of $\rho_i$ at $\mathcal{R}$ and $\mathcal{T}_i$. Thus, the overall performance of our proposed CQI reporting scheme depends on the pilot-based CQI estimation in the first phase.

**Remark 2.** Scheme B would be preferable if asymmetric broadcast channel is considered, e.g., the SNR of $\mathcal{R} \rightarrow \mathcal{T}_i$ link is much higher than the SNR of $\mathcal{R} \rightarrow \mathcal{T}_j$, $j \neq i$, link. In this case, the reliability of the estimation of $\rho_i$ at $\mathcal{T}_j$ is significantly reduced while the estimation of $\rho_j$ at $\mathcal{T}_i$ can be carried out with an insignificant error. However, using scheme B, the estimation of $\rho_i$ at $\mathcal{T}_j$ can be improved with an increased $\theta_{\rho_j}$ and a reduced $\theta_{\rho_j}$. Note that the loss in the performance of the estimation of $\rho_j$ at $\mathcal{T}_i$ caused by the reduced $\theta_{\rho_j}$ is not significant since the $\mathcal{R} \rightarrow \mathcal{T}_1$ link is at high quality.

**IV. ANALYSIS OF MSE OF ESTIMATED CQI**

In this section, we derive the MSE expression of estimated CQI of scheme B. The MSE analysis of scheme A can be similarly carried out. For simplicity, we study the CQI estimation at $\mathcal{T}_2$ only. The analysis of the CQI estimation at $\mathcal{T}_1$ can be similarly obtained. The estimation error occurs if the estimated $\rho_{1,\mathcal{R}}$ at $\mathcal{T}_2$ in the second phase (i.e., $\hat{\rho}_{1,\mathcal{R}}$) is different from the value of $\rho_1$ estimated at $\mathcal{R}$ in the first phase (i.e., $\rho_{1,\mathcal{R}}$). Thus, the MSE of estimated CQI can be computed by

\[
\text{MSE} = \mathbb{E}\left\{[\hat{\rho}_{1,\mathcal{R}} - \rho_{1,\mathcal{R}}]^2\right\},
\]

where $\mathbb{E}\{\cdot\}$ denotes the expectation.

In order to deduce the MSE, we observe that it is difficult to derive $\hat{\rho}_{1,\mathcal{R}}$ and $\rho_{1,\mathcal{R}}$ for any arbitrary characteristics of two links $\mathcal{T}_1 \rightarrow \mathcal{R}$ and $\mathcal{R} \rightarrow \mathcal{T}_2$ simultaneously, however, it is still useful to understand the behaviour of the MSE in an asymptotic case and gain some insights from it. Thus, for simple analysis, let us assume that the link $\mathcal{T}_1 \rightarrow \mathcal{R}$ at a high SNR, i.e., $\gamma_{1dB} = \gamma_{mdB}$; and thus from (2), we can approximate $\rho_1$ by $Q_1$. From (5), the SNR $\gamma_2$ of $\mathcal{R} \rightarrow \mathcal{T}_2$ link can be expressed as

\[
\gamma_2 = \frac{P_R \theta_{\rho_1}}{\sigma_2^2}.
\]

Note that, in the second phase, $\mathbf{x}^{(B)}$ in (5) is constructed by both $\rho_{1,\mathcal{R}}$ and $\rho_{2,\mathcal{R}}$. We assume that $\rho_{2,\mathcal{R}} \approx \rho_{2,\mathcal{T}}$. Since $\rho_{2,\mathcal{T}}$ is known at $\mathcal{T}_2$, it can be removed from the received signal.\footnote{The conventional scheme is referred to as a scheme where $\mathcal{R}$ sequentially transmits $\rho_{1,\mathcal{R}}$ and $\rho_{1,\mathcal{T}}$ to $\mathcal{T}_1$ and then to $\mathcal{T}_2$, respectively, in two time slots.}
Applying (17) to (14), MSE is upper-bounded by
\[ \hat{\rho}_1, \hat{\gamma}_1 \approx \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]. \]
(13)
Substituting (13) into (11) with \( \rho_1, \gamma \approx Q_1 \), we have
\[ \text{MSE} \approx E \left\{ Q_1 - \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]^2 \right\}. \]
(14)

Thus, it can be approximated that \( \rho_1, \gamma \) determines the mapping of \( \rho_1, \gamma \), i.e.,
\[ \rho_1, \gamma = \left( Q_1 - \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]^2 \right). \]
(15)

MSE can be approximated as
\[ \text{MSE} = E \left\{ Q_1 - \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]^2 \right\}. \]
(16)

Let \( \alpha = e^{-\gamma_m/\gamma}, \beta = e^{-1/\gamma}, \gamma_m = 10^{-\gamma_{dn}/10}, Q_1 = 10Q_1/(\gamma_{mdB} \ln 10), Q_1' = Q_1 - Q_1' \ln(\theta_n) \) where \( \gamma \) is average SNR, \( \ln x \) is natural logarithm of \( x \), \( E_i(\cdot) \) is exponential integral, and \( \Theta_{m,n}^{(a_1,\ldots,a_p,z)} \) is Meijer G function [12]. We have the following finding:

**Theorem 1.** The MSE given in (14) is upper-bounded and lower-bounded by \( \text{MSE}_u \) and \( \text{MSE}_l \), respectively, where
\[ \text{MSE}_u = \lambda_1 + \lambda_2 A + \lambda_3 B, \]
(17)
\[ \text{MSE}_l = \lambda_1' + \lambda_2' A + \lambda_3' B, \]
(18)
\[ \lambda_1 = \left[ Q_1 - Q_1' \ln 5 \right]^{2/(\beta - \alpha)}, \lambda_2 = -2Q_1' \ln Q_1', \lambda_3 = Q_1^2, \]
\[ \lambda_1' = \left[ Q_1 - Q_1' \ln 5 \right]^{2/(\beta - \alpha)}, \lambda_2' = -2Q_1' \ln Q_1', \lambda_3 = Q_1^2, \]
\[ A = \beta \ln(\ln Q_1') - \alpha \ln(\ln Q_1') + E_1(\ln Q_1') - E_1(\ln \beta), \]
\[ B = \beta \ln^2(\ln Q_1') - \alpha \ln^2(\ln Q_1') - 2 \ln(\ln Q_1') \Theta_{1,2}^{0,0} \left( \frac{1}{0,0} - \ln Q_1' \right) \]
\[ + 2 \ln(\ln Q_1') \Theta_{1,2}^{0,0} \left( \frac{1}{0,0} - \ln Q_1' \right) - 2 \Theta_{1,3}^{0,0} \left( \frac{1}{0,0,0} - \ln Q_1' \right) \]
\[ + 2 \Theta_{2,3}^{0,0} \left( \frac{1}{0,0,0} - \ln Q_1' \right). \]

**Proof:** We notice that \( \left[ x \right] \geq x \forall x \). Thus,
\[ Q_1 \geq \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right] \geq \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \geq 0. \]
(19)

Applying (17) to (14), MSE is upper-bounded by
\[ \text{MSE}_u = E \left\{ Q_1 - 10^\gamma \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]^2 \right\}. \]
(20)

Another inequality concerning with ceiling function is that
\[ 0 \leq \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right] - 1 - \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} + 1. \]
(21)
The lower bound of MSE is then given by
\[ \text{MSE}_l = E \left\{ Q_1 - 1 - \left[ \frac{10 \log_{10}(\gamma_2)}{\gamma_{mdB}/Q_1} \right]^2 \right\}. \]
(22)

We observe that the expression of MSE is in the same form of \( \text{MSE}_u \) in (18). Thus, MSE in (16) can be similarly obtained.

**Remark 3.** MSE bounds increase as a function of \( Q_1^2 \). From Theorem 1, \( \lambda_1, \lambda_2, \lambda_1', \lambda_2' \), and \( \lambda_3 \) depend on \( Q_1 \), whereas \( A \) and \( B \) are independent of \( Q_1 \). We observe that \( \text{MSE}_u \) and MSE can be rewritten as a function of \( Q_1^2 \), i.e., \( \text{MSE}_u = \zeta Q_1^2 \) and MSE in (16) can be similarly obtained.

**V. EXTENSION TO TWMRNs**

Let us consider a TWMRN including \( N \) relay nodes \( \{R_1, \ldots, R_N\} \). In the proposed relay selection scheme, only the best relay is opportunistically selected to perform the network coding between two terminal nodes. Specifically, an optimal scheme is proposed where the relay is chosen to minimize the sum-MSE given by \( \text{MSE}_u(n) = \text{MSE}_l(n) \). Let \( n \) be the MSE of the estimated CQI at \( T_j \), \( i, j \in \{1, 2\}, i \neq j, j \) in a TWSRN using \( R_n, n \in \{1, \ldots, N\} \). Thus, the optimal relay selection is represented by
\[ n^* = \arg \min_n \text{MSE}(n). \]
(23)

However, the computation complexity of this scheme is high. Let us consider a suboptimal relay selection scheme based on the maximum of MSE or max-MSE. In fact, it is well-known that minimizing the sum can be approximated to minimizing the maximum. Therefore, the relay can be approximately determined by
\[ n_{sub}^* = \arg \min_n \text{MSE}(n), \]
(24)

where \( \text{MSE}(n) = \max_n \{ \text{MSE}_1(n), \text{MSE}_2(n) \} \).

Due to the quantization carried out in the mapping process as explained for TWSRN, we can derive the upper and lower bounds of \( \min_n \text{MMSE}(n) \) or \( \text{MSE}(n_{sub}^*) \). For simple analysis, we assume that scheme A is applied at each relay, \( Q_1 \) and \( Q_2 \) are equal, and, \( \gamma_1(n) \) and \( \gamma_2(n) \) have the same probability density function. Letting \( \alpha = e^{-\gamma_m/\gamma}, \beta = e^{-2/\gamma}, Q_1 = Q_2 \), and \( Q' = 10Q_1/(\gamma_{mdB} \ln 10) \), we have the following finding:

**Theorem 2.** \( \text{MSE}(n_{sub}^*) \) is upper-bounded and lower-bounded by \( \text{MSE}_u(n_{sub}^*) \) and \( \text{MSE}_l(n_{sub}^*) \), respectively, where
\[ \text{MSE}_u(n_{sub}^*) = \lambda_1 + \lambda_2 A + \lambda_3 B, \]
(25)
\[ \text{MSE}_l(n_{sub}^*) = \lambda_1' + \lambda_2' A + \lambda_3' B, \]
(26)
\[ \lambda_1 = [Q - Q' + \gamma_2]/[1 - (\alpha N)(1 - (\beta N)^N)]. \]
Remark 4. The MSE performance of the suboptimal scheme converges to zero when the number of relays is large. It can be seen that \( \lambda_{1N} \rightarrow 0, \lambda'_{1N} \rightarrow 0, A_N \rightarrow 0, \) and \( B_N \rightarrow 0 \) as \( N \rightarrow \infty \). Thus, \( \text{MSE}_u(n_{sub}^*) \rightarrow 0 \) and \( \text{MSE}_l(n_{sub}^*) \rightarrow 0 \). Since \( \text{MSE}_u(n_{sub}^*) \geq \text{MSE}(n_{sub}^*) \geq \text{MSE}_l(n_{sub}^*) \), we can deduce that \( \text{MSE}(n_{sub}^*) \rightarrow 0 \) as \( N \rightarrow \infty \). We can also deduce that the bounds are tighter as \( N \) increases.

Based on the bounds of \( \text{MSE}(n_{sub}^*) \) given in Theorem 2 and their characteristics discussed in Remark 4, we propose a so-called suboptimal bound-based relay selection scheme to reduce the complexity of the searching method in (24). Note that if the previously mentioned suboptimal relay selection scheme (i.e., (24)) is used, \( N \) relays would be verified to choose the best one to minimize the MMSE. Instead, the proposed suboptimal bound-based relay selection will stop the searching when finding out a relay with MMSE being smaller than \( \text{MSE}_u(n_{sub}^*) \). As the result, the number of iterations is significantly reduced, especially with larger \( N \) (i.e., when \( \text{MSE}_u(n_{sub}^*) \) decreases). The complexity reduction will be shown and further discussed in the simulation results.

VI. NUMERICAL RESULTS

Let us first consider the TWSRNs where the CQI estimation is carried out at \( T_2 \). The estimation error occurs if the estimated CQI \( 1 \) at \( T_2 \) is different from the CQI \( 1 \) estimated at \( R \). For comparison, the conventional scheme is applied to the same relay model (i.e., two-way data exchange between two terminals through one relay). Using the conventional scheme, CQI of the link \( T_1 \rightarrow R \) is fed back to \( T_2 \) through one feedback link, and CQI \( 2 \) is separately fed back to \( T_1 \) through another link, which results in heavy overhead. Using our proposed schemes, combined data broadcasted from relay \( R \) enables each terminal to estimate the required CQI. This process utilises only one time slot and requires no additional overhead.

As shown in Fig. 1, the MSE of estimated CQI \( 1 \) of various schemes is drawn against the SNR of \( R \rightarrow T_2 \) link with the assumption that \( Q_1 = Q_2 = 8 \) and \( \gamma_{mdB} = 20 \) dB. The SNRs of the \( T_1 \rightarrow R \) and \( T_2 \rightarrow R \) links are assumed to be 20 dB, and, the SNRs of the \( R \rightarrow T_1 \) and \( R \rightarrow T_2 \) links are subject to have sum of 20 dB. First, the upper and lower bounds given by (15) and (16) are shown to be quite tight and reflect well the behavior of the numerical MSEs. We can observe that the performance of our proposed schemes is close to the conventional scheme, especially at high SNR. The expected small loss is explained in Remark 1. Finally, comparing between scheme A and scheme B, we observe that a better performance can be achieved with scheme B when the SNR of \( R \rightarrow T_2 \) link is less than 10 dB. This confirms the explanation in Remark 2.

Next, we consider the TWMRNs where multiple relays are taken into account. For relay selection, the optimal scheme in (23), the suboptimal max-MMSE based scheme in (24), and the proposed suboptimal bound-based scheme are used. For CQI estimation, the conventional scheme for the TWMRNs is also considered. We assume that \( Q_1 = Q_2 = 16 \) and the SNRs of the \( R \rightarrow T_1 \) and \( R \rightarrow T_2 \) links are 4 dB. As shown in Fig. 2, the performances with different selection schemes are
\[ A_N = (-1)^N \sum_{m=1}^{N} (-1)^{m-1} \frac{\Gamma_j^{-1} (N - j + 1)}{(m - 1)!} \left\{ E_i [(N - m + 1) \ln \alpha_N] - E_i [(N - m + 1) \ln \beta_N] \right\}, \]

\[ B_N = (-1)^N \sum_{m=1}^{N} (-1)^{m-1} \frac{\Gamma_j^{-1} (N - j + 1)}{(m - 1)!} \left\{ \alpha_N^{N-m+1} \ln (-\ln \alpha_N) + \beta_N^{N-m+1} \ln (-\ln \beta_N) \right\}, \]

\[ + 2 \ln(-\ln \alpha_N) \theta_{2,0}^{2,0} \left( \frac{1}{0,0} \right) - (N - m + 1) \ln \beta_N \]

\[ - 2 \theta_{2,3}^{2,3} \left( \frac{1,1}{0,0,0} \right) - (N - m + 1) \ln \beta_N \]

\[ \text{Fig. 2. MSE versus number of relays (N) with different relay selection schemes.} \]

\[ \text{Fig. 3. Number of iterations versus number of relays (N) with suboptimal and suboptimal bound-based relay selection schemes.} \]

The complexity advantage of the proposed suboptimal bound-based relay selection scheme is shown in Fig. 3, especially when the number of relays in TWMRs is large. For example, the proposed scheme is significantly reduced compared to that of the searching algorithm in (24), especially when the number of relays in TWMRNs is large. For example, the complexity is reduced by at least three times if the number of relays is larger than five.

VII. Conclusion

In this paper, we proposed and discussed two efficient CQI reporting schemes in nonregenerative TWSRNs based on XOR and superposition coding. These schemes reduce the transmission time by half while incurring no additional overhead. Significantly, these throughput advantages are obtained at the expense of negligible performance loss. In addition, the upper and lower bounds of the MSE of estimated CQI are derived. The bounds are shown to be tight and reflect well the behavior of the numerical MSE curves. Furthermore, a suboptimal bound-based relay selection scheme is proposed for TWMRNs to reduce the searching complexity of the optimal scheme. The performance of the proposed selection scheme is shown to be close to that of the optimal one while reducing the complexity by at least three times if the number of relays is larger than five. For future work, one can investigate the system model including the direct link between two terminals and consider the scenario where the channels are not completely reciprocal.
